# Background Study

---

## What is a MAC and its purpose in data integrity/authentication?

A **Message Authentication Code (MAC)** is a cryptographic technique used to:

- Verify the **integrity** of a message
- Confirm the **authenticity** of the sender

The MAC is created using a **secret key** and the message content. It produces a fixed-size output called the MAC value. The recipient, who also knows the key, recalculates the MAC to verify the message.

## Purpose:

- **Integrity** – Detects message modifications
- **Authentication** – Confirms sender identity
- **Non-repudiation** – Prevents sender denial (in some cases)

## Common MAC types:

- **HMAC** (Hash-based MAC): Combines hash functions like SHA-256 with a secret key
  - **CBC-MAC** (Cipher Block Chaining MAC): Uses block ciphers
- 

## How does a length extension attack work in hash functions like MD5/SHA1?

A **length extension attack** targets hash functions like MD5 and SHA-1 that use the Merkle-Damgård structure.

These hash functions process input in blocks. The internal state after processing one block is used for the next.

## Steps:

1. Attacker knows:

**$H = \text{hash}(\text{secret} \parallel \text{message})$**

and the length of  **$\text{secret} \parallel \text{message}$**

2. Attacker appends new data:

**$\text{message} \parallel \text{padding} \parallel \text{new\_data}$**

The padding aligns the total length to the block size.

3. Attacker uses **H** as the internal state and calculates:

**$H' = \text{hash}(H \parallel \text{padding} \parallel \text{new\_data})$**

4. **H'** is valid for:

**$\text{secret} \parallel \text{message} \parallel \text{padding} \parallel \text{new\_data}$**

without knowing the secret.

## Vulnerable functions:

- MD5
- SHA-1
- SHA-256

**Safe against this:** HMAC and other special constructions

---

## Why is $\text{MAC} = \text{hash}(\text{secret} \parallel \text{message})$ insecure?

Using  $\text{MAC} = \text{hash}(\text{secret} \parallel \text{message})$  is vulnerable to length extension attacks.

### Why:

The hash's internal state after processing  $\text{secret} \parallel \text{message}$  can be reused. Attackers can create valid MACs for longer messages without knowing the secret.

### Example:

If

$\text{MAC} = \text{SHA1}(\text{secret} \parallel \text{message})$

An attacker can forge a valid MAC for:

$\text{secret} \parallel \text{message} \parallel \text{padding} \parallel \text{new\_data}$

### Fixes:

- **HMAC** – Uses nested hashing to break the chain  
 $\text{HMAC} = \text{hash}(\text{outer\_key} \parallel \text{hash}(\text{inner\_key} \parallel \text{message}))$
- **Truncation** – Shortens the MAC to hide internal states
- **Alternative MACs** – Use SHA-3-based KMAC or CBC-MAC
